The application domain: the agronomic crop model STICS

STICS simulates the behaviour of the soil-crop system over one or successive crop cycles.

Objectives

to simulate consequences on crop production and environment of variations in: climate, soil, and crop management

Simulated object (Control Parameters)

a cultural situation = a soil-crop system + a technical itinerary

Simulated processes (Outputs)

- ↪ growth and development of the crop
- ↪ water and nitrogen balance of the soil-crop system

Key output variables of STICS

LAI: Leaf Area Index

Total one-sided area of leaf tissue per area of ground surface.

Leaves are the main interface with the atmosphere for the transfer of mass and energy
⇒ the LAI indirectly describes:

- potential of photosynthesis available for primary production
- plant respiration, evapotranspiration
- biosphere ↔ atmosphere carbon flux.
- severely affected areas (fires, parasites...)

LAI closely related to:

Biomass

Total mass of living matter per area of land.

LAI of wheat over a year

Observed LAI (from inversion of radiative transfer model)

Sensitivity analysis: what it is and what for?

Sensitivity analysis is an initial goal

↪ further goals include (≈ 200) parameter estimation

Sensitivity analysis studies the impact of perturbing the control (input) parameters on the model output. It helps to:

- prioritize the model parameters
- identify critical regions in the space of the inputs (including interactions)
- support decision for research and future experiments.
↪ which parameters deserve accurate measurements?
- gauge model adequacy and physical relevance
- simplify models (metamodeling)
- find technical errors in the model

Sensitivity analysis: mathematical framework

- A model:

$$F(X, K) = 0$$

X = state variables (LAI, biomass ...)

K = control variables (parameters, forcing variables ...)

Here, the *model* is exactly the *STICS computer program* $K \mapsto X$.

- A response function $G(X)$, e.g.

$$G_{LAI} = \sum_{i=1}^T LAI(t_i) \quad \text{or} \quad G_{biomass} = \sum_{i=1}^T biomass(t_i)$$

The problem is to evaluate the sensitivity of G with respect to K
or in other words the gradient of G with respect to K .

With an adjoint model, **only 2 steps**:

- 1 run the direct model once for the given K
- 2 solve the adjoint model

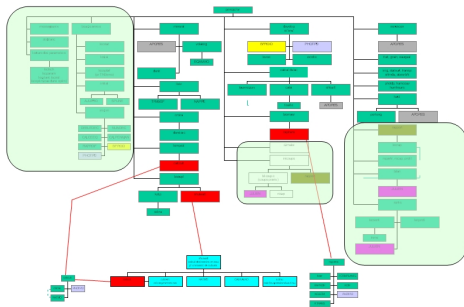

$$\nabla G = \frac{dG}{dK} = \left(\frac{dG}{dX} \cdot \frac{dX}{dK} \right)^t = \boxed{\left(\frac{dX}{dK} \right)^t} \cdot \boxed{\left(\frac{dG}{dX} \right)^t}$$

Sensitivity analysis: adjoint model or other approaches?

Adjoint method is the only way to calculate formally the gradient of the response function at a cost that does not depend on the size of K
 \Rightarrow appropriate when number of entries $K \gg$ size of response function

other approach	advantages	disadvantages
tangent-linear	no need to calculate the adjoint	cost proportional to the size of K
finite difference	easy calculations	approximation of the gradient + extensive direct model computations
stochastic sampling techniques	global sensitivity	cost grows rapidly with the dimension of K

Practical problems with models like STICS

Function:

Derivative:

Piecewise differentiable function

⇒ only left- and right-derivatives (or sub-gradients)

↪ Derivative-free methods (divided differences, stochastic, ...) behave better in these cases, but at a cost.

↪ In practice, problem is overlooked: local sensitivity valid in a neighborhood of K .

Selected input parameters for sensitivity analysis

parameter	definition	value
<i>dlaimaxbrut</i>	maximum rate of gross leaf surface area production	0.00044
<i>stlevamf</i>	cumulated development units between the LEV and AMF stages	208.298
<i>stamflax</i>	cumulated development units between AMF and LAX stages	181.688
<i>jvc</i>	days of vernalisation (cold days needed to lift)	35
<i>durvieF</i>	lifespan of a cm of adult leaf	160
<i>adens</i>	compensation between number of stems and plants density	-0.6
<i>efcroijuv</i>	maximum growth efficiency during juvenile phase (LEV-AMF)	2.2
<i>efcroiveg</i>	maximum growth efficiency during vegetative phase (AMF-DRP)	2.2
<i>efcroirepro</i>	maximum growth efficiency during grain filling phase (DRP-MAT)	4.25
<i>vmax2</i>	maximum rate of nitrate absorption by the roots	0.05

All these parameters would deserve a good parameter estimation...

Plan

- 1 The application domain: the agronomic crop model STICS
- 2 Sensitivity analysis of STICS
 - Sensitivity analysis: what it is and what for?
 - Selected input parameters for sensitivity analysis
- 3 Automatic Differentiation of STICS

 - STICS adjoint: the pains and sufferings of an AD end-user
 - Validation of the adjoint model
- 4 Conclusion
 - Sensitivity results of LAI and biomass
 - Benefits

TAPENADE

We build the adjoint of STICS with TAPENADE.

TAPENADE (2.0 at the time, now 3.6):

- Automatic Differentiation by source-to-source transformation
- Flow- and Context-sensitive global data-flow analysis
- Association by name
- Adjoint with Store-All strategy
- Checkpointing on calls by default

A few recommended programming practices

STICS is FORTRAN 77 \Rightarrow In theory, TAPENADE can build its adjoint

- \rightsquigarrow but improvements required on old TAPENADE (< 2005),
- \rightsquigarrow plus some adaption of STICS

Adaption of STICS source:

- Active vars should be separate from others: no big work array !
- Active independents and dependents must be clearly identified
 \Rightarrow keep them **separate** from the other variables.
- Use a coherent precision level: DOUBLE PRECISION
- Solve portability problems unveiled by AD:
no uninitialized **remanent globals** !

Issues due to AD in general

- *the program itself is the equation* (no ODE/PDE)
⇒ conditional jumps with no underlying continuity/differentiability.
- Uncontrolled code evolution
⇒ fast increase of new subcases and subdivisions.

Several subroutines needed manual improvement to Restore differentiability

⇒ a cleaner STICS ?

Issues due to TAPENADE

- Remarkably large number of branches: thresholds, conditions, loops ... that must be stored for control-flow reversal.
⇒ define `PUSHCONTROL()`, cheaper than storing a full `INTEGER`
- Time stepping: split main time loop (400 steps) into nested 20-steps loops. Make them subroutines to force checkpointing
⇒ now with `TAPENADE 3.6`, use `$AD BINOMIAL-CKP`
- Fine-tune checkpointing of nested calls:

⇒ `$AD NOCHECKPOINT`

Co-evolution of STICS and TAPENADE

⇒ a more portable STICS & a more efficient adjoint code

Validation of the adjoint model

<i>Divided Differences:</i>	0.42248278309969720000
<i>Tangent AD:</i>	0.42248278406221984000
<i>Adjoint AD:</i>	0.42248278406222007000

- Performance with TAPENADE 2.0 (2005):

Orig: 0.21 s Tgt: 0.39 s Adj: 30.96 s Traffic: 13.8 Gb
Peak: 240 Mb

- After checkpointing fine tuning (C\$AD NOCHECKPOINT)

Orig: 0.22 s Tgt: 0.52 s Adj: 0.86 s Traffic: 0.2 Gb
Peak: 162 Mb

Plan

- 1 The application domain: the agronomic crop model STICS

 - Validation of the adjoint model
- 4 Conclusion
 - Sensitivity results of LAI and biomass
 - Benefits

Sensitivity results of LAI and biomass

Hierarchy of influent parameters:

- LAI: *adens* is the most influential parameter (47%). It represents the ability of a plant to withstand increasing densities, depends on the species and varieties ⇒ **strong influence for this type of wheat and less for other crops.**
- Biomass: hierarchy modified by the strong influence of the efficiency *efcroiveg* (maximum growth efficiency during vegetative phase) ⇒ **we can ignore the estimate of *efcroiveg* if we only work on LAI, but absolutely not to simulate biomass.**
- relatively low sensitivity (5% and 3%) of biomass integrated over the life cycle to the other 2 parameters of efficiency *efcroirepro* and *efcroijuv* ⇒ **the biomass is not so dependant on the juvenile and the grain filling phases but essentially on the vegetative phase.**
- LAI is actually dependant on 4 params and biomass on 5 ⇒ **the user should concentrate on these and estimate them better. Uncertainty on the other parameters is of smaller importance.**

Conclusion

- For the agronomic community, the adjoint model of STICS is an efficient way to perform sensitivity analysis since it requires the calculation only once for each agro-pedo-climatic situation.
- AD is a choice approach for sensitivity analysis of agronomic models, where the code is the model.
- Sensitivity analysis focuses user's attention on some parameters and modules, according to the user's objectives.
- ! This local sensitivity analysis is local, valid only in a small neighborhood and the hierarchy of sensitivities may vary under different conditions (but in practice: quite stable hierarchy).
- Sensitivity analysis is a preliminary to parameter estimation, data assimilation: many of these agronomic parameters (yield, balance, . . .) are not directly observable
- This shows that variational methods **are applicable in agronomy** but it takes a **truly pluridisciplinary work!**
