Abstract

We propose in this paper a tracking algorithm which is able to adapt itself to different scene contexts. A feature pool is used to compute the matching score between two detected objects. This feature pool includes 2D, 3D displacement distances, 2D sizes, color histogram, histogram of oriented gradient (HOG), color covariance and dominant color. An offline learning process is proposed to search for useful features and to estimate their weights for each context. In the online tracking process, a temporal window is defined to establish the links between detected objects. This enables to find the object trajectories even if the objects are misdetected in some frames. A trajectory filter is proposed to remove trajectories considered as noise. Experimentation on different contexts is shown. The proposed tracker has been tested in seven videos (in which five sequences belong to the ETISEO [2] and Caviar [1] datasets). The experimental results prove the effect of the proposed feature weight learning, and the robustness of the proposed tracker compared to some methods in the state of the art. The contributions of our approach over the state of the art trackers are: (i) a robust tracking algorithm based on a feature pool, (ii) a supervised learning scheme to learn feature weights for each context, (iii) a new method to quantify the reliability of HOG descriptor, (iv) a combination of color covariance and dominant color features with spatial pyramid distance to manage the case of object occlusion.

1 Introduction

Many approaches have been proposed to track mobile objects in a scene [5]. The problem is to know whether these approaches can perform well in different scene conditions (e.g. different people density levels, different illumination conditions). And in those cases, how can the user tune parameters to get the best possible tracking result?

The ideas about an automatic control system have been studied to adapt the algorithm to the context variations [15, 8, 12]. In [15], the authors have presented a framework which is able to integrate knowledge and uses it to control the image processing programs. However, the construction of a knowledge base for this system requires a lot of time and data. Also, their study is restricted to static image processing (no video). In [8], the authors have presented an architecture for a self-adaptive perceptual system in which the "auto-criticism" stage plays the role of an online evaluation process. To do that, the system computes trajectory goodness score based on clusters of typical trajectories. Therefore, this method can be only applied for the scenes where mobile objects move on well defined paths, roads... In [12], the authors have presented a tracking framework which is able to control a set of different trackers to get the best possible performance. The approach is interesting but the authors do not mention how to evaluate online the tracker quality. Also, the execution of three trackers in parallel is very expensive in terms of processing time.

In order to overcome these limitations, we propose a tracking algorithm that is able to adapt itself to different contexts. The notion of context mentioned in this paper includes a set of scene properties: density of mobile objects, frequence of occlusion occurrences, illumination intensity, contrast level and the depth of the scene. These properties have a strong effect on the tracking quality. In order to be able to track object movements in different contexts, we define firstly a feature pool in which each weighted feature combination can help the system to outperform its performance in each context. However, the determination of feature weight values is a hard task because the user has to quantify correctly the importance of each feature in the considered context. To facilitate this task, we propose an offline learning algorithm based on Adaboost [7] to compute feature weight values for each context.

The paper rest is organized as follows: The next section presents the feature pool and explains how to use it to compute link similarity between detected objects. Section 3 describes the offline learning process to tune the feature weights for each scene context. Section 4 shows in detail the different stages of the tracking process. The results of the experimentation and validation can be found in section 5. A conclusion as well as future work are given in the last section.

2 Feature pool and link similarity

2.1 Feature pool

The principle of the proposed tracking algorithm is based on the coherence of mobile object features throughout time. In this paper, we define a set of 8 different features to compute a link similarity between two mobile objects l and m within a temporal window (see figure 1).

2.1.1 2D and 3D displacement distance similarity

Depending on the object type (e.g. car, bicycle, walker), the object speed cannot exceed a fixed threshold. Let D_{max} be the possible maximal 3D displacement of a mobile object for 1 frame in a video and d be the 3D distance of two considered objects, we define a similarity LS_1 between these two objects using the 3D displacement distance feature as follows:

$$LS_1 = max(0,\ 1 - d/(D_{max} * n)) \tag{1}$$

where n is the temporal difference (frame unity) of the two considered objects.

Similarly, we also define a similarity LS_2 between two objects using displacement distance feature in the 2D image coordinate system.

2.1.2 2D shape ratio and area similarity

Let W_l and H_l be the width and height of the 2D bounding box of object l. The 2D shape ratio and area of this object are respectively defined as W_l/H_l and W_lH_l. If no occlusions occur and mobile objects are well detected, shape ratio and area of a mobile object within a temporal window does not vary much even if the lighting and contrast conditions are not good. A similarity LS_3 between two 2D shape ratios of objects l and m is defined as follows:

$$LS_3 = min(W_l/H_l,\ W_m/H_m)/max(W_l/H_l,\ W_m/H_m) \tag{2}$$

Also we define the similarity LS_4 between two 2D areas of objects l and m as follows:

$$LS_4 = min(W_lH_l,\ W_mH_m)/max(W_lH_l,\ W_mH_m) \tag{3}$$

2.1.3 Color histogram similarity

In this work, the color histogram of a mobile object is defined as a normalized RGB color histogram of moving pixels inside its bounding box. We define a link similarity LS_5 between two objects l and m for color histogram feature as follows:

$$LS_5 = \frac{\sum_{k=1}^{3\times R} min(H_l(k), H_m(k))}{3} \tag{4}$$

where R is a parameter representing the number of histogram bins for each color channel ($R = 1..256$), $H_l(k)$ and $H_m(k)$ are respectively the histogram values of object l, m at bin k.

2.1.4 HOG similarity

In case of occlusion, the system may fail to detect the full appearance of mobile objects. The above features are then unreliable. In order to address this issue, we propose to use the HOG descriptor to track locally interest points on mobile objects and to compute the trajectory of these points. The HOG similarity between two objects is defined as a value proportional to the number of pairs of tracked points belonging to both objects. In [11], the authors propose a method to track FAST points based on their HOG descriptors. However the authors do not compute the reliability level of the obtained point trajectories. In this work, we define a method to quantify the reliability of the trajectory of each interest point by considering the coherence of the Frame-to-Frame (F2F) distance, the direction and the HOG similarity of the points belonging to a same trajectory. We assume that the variation of these features follows a Gaussian distribution.

Let $(p_1, p_2, ..., p_i)$ be the trajectory of a point. Point p_i is on the current tracked object and point p_{i-1} is on an object previously detected. We define a coherence score S_i^{dist} of F2F distance of point p_i as follows:

$$S_i^{dist} = \frac{1}{\sqrt{2\pi\sigma_i^2}} e^{-\frac{(d_i-\mu_i)^2}{2\sigma_i^2}} \tag{5}$$

where d_i is the 2D distance between p_i and p_{i-1}, μ_i and σ_i are respectively the mean and standard deviation of the F2F distance distribution formed by the set of points $(p_1, p_2, ..., p_i)$.

In the same way, we compute the direction coherence score S_i^{dir} and the similarity coherence score S_i^{desc} of each interest point. Finally for each interest point p_i on the tracked object l, we define a coherence score S_i^l as the mean value of these three coherence scores.

Let P be the set of interest point pairs which trajectories pass through two considered objects o_l and o_m; S_i^l (S_j^m respectively) be the coherence score of point i (j respectively) on object l (m respectively) belonging to set P. We defne the similarity of HOG between these two objects as follows:

$$LS_6 = min(\frac{\sum_{i=1}^{|P|} S_i^l}{M_l}, \frac{\sum_{j=1}^{|P|} S_j^m}{M_m}) \tag{6}$$

where M_l and M_m are the total number of interest points detected on objects l and m.

2.1.5 Color covariance similarity

Color covariance is a very useful feature to characterize the appearance model of an image region. The covariance matrix of any region with the same feature set will have the same matrix size, thus it enables the comparison of regions with different sizes. The covariance is invariant to the changes of the feature mean such as identical shifting of color values. This becomes an advantageous property when objects are tracked under varying illumination conditions. In [13], for a feature point i in a given image region R, the authors define a covariance matrix C_i corresponding to 11 following features: $\{x, y, R_{xy}, G_{xy}, B_{xy}, M_{xy}^R, O_{xy}^R, M_{xy}^G, O_{xy}^G, M_{xy}^B, O_{xy}^B\}$ where (x, y) is pixel location, R_{xy}, G_{xy}, and B_{xy} are RGB channel values, and M, O correspond to gradient magnitude and orientation in each channel at position (x, y).

We use the distance defined by [6] to compare two covariance matrices:

$$\rho(C_i, C_j) = \sqrt{\sum_{k=1}^{F} ln^2 \lambda_k(C_i, C_j)} \tag{7}$$

where F is the number of considered features ($F = 11$ in this case), $\lambda_k(C_i, C_j)$ is the generalized eigenvalue of C_i and C_j.

In order to take into account the spatial coherence of the color covariance distance and also to manage occlusion cases, we propose to use the spatial pyramid distance defined in [9]. The main idea is to divide the image region of a considered object by a set of sub-regions. For each level i ($i \geq 0$), the considered region is divided by a set of 2^i x 2^i sub-regions. Then we compute the local color covariance distance for each pair of corresponding sub-regions. The computation of each sub-region pair helps to evaluate the spatial structure coherence between two considered objects. In the case of occlusions, the color covariance distance between two regions corresponding to occluded parts will be very high. Therefore, we take only a half of the lowest color covariance distances (i.e. highest similarities) for each level to compute the final color covariance distance.

The similarity of this feature is defined as a function of the spatial pyramid distance:

$$LS_7 = max(0,\ 1 - d_{cov}/D_{cov\_max}) \tag{8}$$

where d_{cov} is the spatial pyramid distance of the color covariance between two considered objects, and D_{cov_max} is the maximum distance for two color covariance matrices to be considered as similar.

2.1.6 Dominant color similarity

Dominant color descriptor (DCD) has been proposed by MPEG-7 and is extensively used for image retrieval [10]. This is a reliable color descriptor because it takes into account only important colors of the considered image region. DCD of an image region is defined as $F = \{\{c_i, p_i\},\ i = 1..A\}$ where A is the total number of dominant colors in the considered image region, c_i is a 3D RGB color vector, p_i is its occurrence percentage, with $\sum_{i=1}^{A} p_i = 1$.

Let F_1 and F_2 be the DCDs of two image regions of considered objects. The dominant color distance between these two regions is defined using the similarity measure proposed in [10]. Also, similar to the color covariance feature, in order to take into account the spatial coherence and also occlusion cases, we propose to use the spatial pyramid distance for the dominant color feature. The similarity of this feature is defined in the function of the spatial pyramid distance as follows:

$$LS_8 = 1 - d_{DC} \tag{9}$$

where d_{DC} is the spatial pyramid distance of dominant colors between two considered objects.

2.2 Link similarity

Using the eight features we have described above, a link similarity $LS(o_l,\ o_m)$ is defined as a weighted combination of feature similarities LS_i between objects o_l and o_m:

$$LS(o_l,\ o_m) = \frac{\sum_{k=1}^{8} w_k LS_k}{\sum_{k=1}^{8} w_k} \tag{10}$$

where w_k is the feature weight (corresponding to its efficiency), at least one weight is not null.

3 Learning feature weights

Each feature described above is efficient for some particular context conditions. However, how can the user quantify correctly the feature significance for a given context? In order to address this issue, we propose in this paper an offline supervised learning process using the Adaboost algorithm [7]. Each feature is considered as a weak classifier. The expected output of the learning phase is a strong classifier which combines these 8 weak classifiers with their weights.

In the learning phase, we choose a video sequence whose context is similar to the considered context. First, for each object pair (o_l, o_m) (called a training sample) denoted op_i ($i = 1..N$) in two consecutive frames, we classify it into two classes {+1, -1}: $y_i = +1$ if the pair belongs to the same tracked object and $y_i = -1$ otherwise. For each feature k ($k = 1..8$), we define a classification mechanism for a pair op_i as follows:

$$h_k(op_i) = \begin{cases} +1 \ \ if\ LS_k(o_l,\ o_m) \geq Th_1 \\ -1 \ \ otherwise \end{cases} \tag{11}$$

where $LS_k(o_l,\ o_m)$ is the similarity score of feature k (defined in section 2.1) between two objects o_l and o_m, Th_1 is a predefined threshold representing the minimum feature similarity considered as similar.

The loss function for Adaboost algorithm at iteration z for each feature k is defined as:

$$\epsilon_k = \sum_{i=1}^{N} D_z(i) max(0, -y_i h_k(op_i)) \tag{12}$$

where $D_z(i)$ is the weight of training sample op_i at iteration z. At each iteration z, the goal is to find k whose loss function ϵ_k is minimum. h_k and ϵ_k (corresponding to value k found) are denoted h_z and ϵ_z. The weight of this weak classifier denoted α_z is computed as follows:

$$\alpha_z = \frac{1}{2} ln \frac{1 - \epsilon_z}{\epsilon_z} \tag{13}$$

We then update the weight of samples:

$$D_{z+1}(i) = \begin{cases} 1/N\ , & if\ z = 0 \\ \frac{D_z(i) exp(-\alpha_z y_i h_z(op_i))}{A_z}, & otherwise \end{cases} \tag{14}$$

where A_z is a normalization factor so that $\sum_i^N D_{z+1}(i) = 1$.

At the end of the Adaboost algorithm, the feature weights are determined for the considered context and allow to compute the link similarity defined in formula 10.

4 The proposed tracking algorithm

The proposed tracking algorithm needs a list of detected objects in a temporal window as input. The size of this temporal window (denoted T_2) is a parameter. The proposed tracker

is composed of three stages. First, the system computes the link similarity between any two detected objects appearing in a given temporal window to establish possible links. Second, the trajectories that include a set of consecutive links resulting from the previous stage, are then computed as the system gets the highest possible total of global similarities (see section 4.3). Finally, a filter is applied to remove noisy trajectories.

4.1 Establishment of object links

For each detected object pair in a given temporal window of size T_2, the system computes the link similarity (i.e. instantaneous similarity) defined in formula 10. A temporal link is established between these two objects when their link similarity is greater or equal to Th_1 (presented in equation 11). At the end of this stage, we obtain a weighted graph whose vertices are the detected objects in the considered temporal window and whose edges are the temporally established links associated with the object similarities (see figure 1).

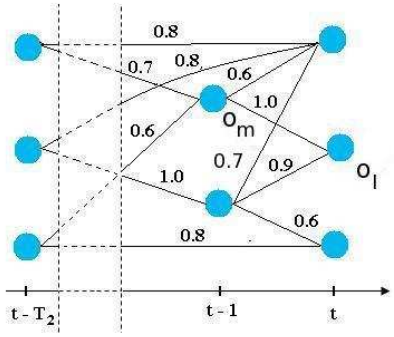

Figure 1. The graph representing the established links of the detected objects in a temporal window of size T_2 frames.

4.2 Long term similarity

In this section, we study similarity score between an object o_l detected at t and the trajectory of o_m detected previously, called long term similarity (to distinguish with the link similarity score between two objects). By assuming that the variations of the 2D area, shape ratio, color histogram, color covariance and dominant color features of a mobile object follow a Gaussian distribution, we can use the Gaussian probability density function (PDF) to compute this score. Also, longer the trajectory of o_m is, more reliable this similarity is. Therefore, for each feature k in these features, we define a long term similarity score between object o_l and trajectory of o_m as follows:

$$LT_k(o_l,\ o_m) = \frac{1}{\sqrt{2\pi\sigma_m^2}} e^{-\frac{(s_l-\mu_m)^2}{2\sigma_m^2}} min(\frac{T}{Q}, 1) \qquad (15)$$

where s_l is the value of feature k for object l, μ_m and σ_m are respectively mean and standard deviation values of feature k of last Q-objects belonging to the trajectory of o_m (Q is a predefined parameter), T is time length (number of frames) of o_m trajectory. Thanks to the selection of the last Q-objects, the long term similarity can take into account the latest variations of the o_m trajectory.

For the left features (2D, 3D displacement distance and HOG), the long term similarity are set to the same values of link similarity.

4.3 Trajectory determination

The goal of this stage is to determine the trajectories of the mobile objects. For each detected object o_l at instant t, we consider all its matched objects o_m (i.e. objects with temporal established links) in previous frames that do not have yet official links (i.e. trajectories) to any objects detected at t. For such an object pair $(o_l,\ o_m)$, we define a global score $GS(o_l,\ o_m)$ as follows:

$$GS(o_l,\ o_m) = \frac{\sum_{k=1}^{8} w_k GS_k(o_l,\ o_m)}{\sum_{k=1}^{8} w_k} \qquad (16)$$

where w_k is the weight of feature k (resulting from learning phase, see section 3), $GS_k(o_l,\ o_m)$ is the global score of feature k between o_l and o_m, defined as a function of link similarity and long term similarity of feature k:

$$GS_k(o_l,\ o_m) = (1-\beta)LS_k(o_l,\ o_m) + \beta LT_k(o_l,\ o_m) \quad (17)$$

where $LS_k(o_l,\ o_m)$ is the link similarity of feature k between the two objects o_l and o_m, $LT_k(o_l,\ o_m)$ is their long term similarity defined in section 4.2, β is the weight of long term similarity and is defined as follows:

$$\beta = min(\frac{T}{Q}, Th_4) \qquad (18)$$

where T, Q are presented in section 4.2, and Th_4 is the maximum expected weight for the long term similarity.

The object o_m having the highest global similarity will be considered as a temporal father of object o_l. After considering all objects at instant t, if more than one object get o_m as a father, the pair $(o_l,\ o_m)$ which $GS(o_l,\ o_m)$ value is the highest will be kept and the link between this pair is official (i.e. become officially a trajectory segment). An object is no longer tracked if it cannot establish any official links in T_2 consecutive frames.

4.4 Trajectory filtering

Noise usually appears when wrong detection or misclassification (e.g. due to low image quality) occurs. Hence a static object (e.g. a chair, a machine) or some image regions (e.g. window shadow) can be detected as a mobile object. However, noise usually only appears in few frames or has no real motion. We thus use temporal and spatial filters to remove potential noises. A trajectory is considered as a noise if one of the following conditions is satisfied:

$$\begin{aligned} T &< Th_5 \\ d_{max} &< Th_6 \end{aligned}$$

where T is time length of the considered trajectory; d_{max} is the maximum spatial length of this trajectory; Th_5, Th_6 are the predefined thresholds.

5 Experimentation and Validation

The objective of this experimentation is to prove the effect of feature weight learning, also to compare the performance of the proposed tracker with some other trackers in the state of the art. To this end, in the first part, we test the proposed tracker with two complex videos (many moving people, high occlusion occurrence frequency) in both cases: without and with the feature weight learning. In the second part, five videos belonging to two public datasets ETISEO and Caviar are experimented, and the tracking result (with the feature learning) is compared with some other approaches in the state of the art.

In order to evaluate the tracking performance, in this work we use the three tracking evaluation metrics defined in the ETISEO project [4]. The first tracking evaluation metric M_1 measures the percentage of time during which a reference object (ground truth data) is correctly tracked. The second metric M_2 computes throughout time how many tracked objects are associated with one reference object. The third metric M_3 computes the number of reference object IDs per tracked object. These metrics must be used together to obtain a complete performance evaluation. Therefore, we also define a tracking metric $\overline{M}$ taking the average value of these three tracking metrics. All of the four metric values are defined in the interval [0, 1]. The higher the metric value is, the better the tracking algorithm performance gets.

In this experimentation, we use the people detection algorithm based on the HOG descriptor of the OpenCV library. Therefore we focus the experimentation on the sequences containing people movements. However the principle of the proposed tracking algorithm is not dependent on tracked object type. For learning feature weights, we use video sequences that are different from the tested videos but which have a similar context.

The first tested video depicts people moving in a subway station (hidden for anonymity reason). The frame rate of this sequence is 5 fps ($frames/second$) and the length is 5 min (see image 2a). We have learnt feature weights on a sequence of 2000 frames. The learning algorithm selects $w_5 = 0.5$ (color histogram feature) and $w_6 = 0.5$ (HOG feature).

The second tested sequence depicts the movements of people in an airport and is provided by TRECVid [3] (see image 2b). It contains 5000 frames and lasts 3 min 20 sec. We have learnt feature weights on a sequence of 5000 frames. The learning algorithm selects $w_1 = 0.24$ (3D distance displacement), $w_4 = 1$ (2D area) and $w_5 = 0.76$ (color histogram).

Table 1 presents the tracking results in two cases: without and with feature weight learning. We can find that with the proposed learning scheme, the tracker performance increases in both tested videos. Also, the processing time of the tracker also decreases significantly because many features are not used. The two following tested videos belong to ETISEO dataset. The first tested ETISEO video shows a building entrance, denoted ETI-VS1-BE-18-C4. It contains 1108 frames and frame rate is 25 fps. In this sequence, there is only one person moving (see image 2c). We have learnt feature weights on a sequence of 950 frames. The learning algorithm has selected the 3D displacement distance feature as the unique feature for tracking in this context. The result of the learning phase is reasonable since there is only one moving person.

The second tested ETISEO video shows an underground station denoted ETI-VS1-MO-7-C1 with occlusions. The difficulty of this sequence consists in the low contrast and bad illumination. The scene depth is quite important (see image 2d). This video sequence contains 2282 frames and frame rate is 25 fps. We have learnt feature weights on a sequence of 500 frames. The color covariance feature is selected as the unique feature for tracking in this context. It is a good solution because the dominant color and HOG feature do not seem to be effective due to bad illumination. Also, the size and displacement distance features are not reliable because their measurements do not seem to be discriminative for far away moving people from the camera.

In these two experiments, tracker results from seven different teams (denoted by numbers) in ETISEO have been presented: 1, 8, 11, 12, 17, 22, 23. Because names of these teams are hidden, we cannot determine their tracking approaches. Table 2 presents performance results of the considered trackers. The tracking evaluation metrics of the proposed tracker get the highest values in most cases compared to other teams.

The last three tested videos belong to the Caviar dataset [1] (see image 2e). In this dataset, we have selected the same sequences experimented in [14] to be able to compare each other: OneStopEnter2cor, OneStopMoveNoEnter1cor and OneStopMoveNoEnter2cor. In these three sequences, there are totally 9 peoples walking in a corridor. The proposed approach can track all of them. However there are three noisy trajectories in the last sequence because of wrong detection occurred in a long period. Table 3 presents the result summary for these videos. TP (True Positive) refers to the number of correct tracked trajectories. FN (False Negative) is the number of lost trajectories. FP (False Positive) represents the number of noisy trajectories. Compared to [14], our proposed tracker have better values in all of these three indexes.

6 Conclusion and Future work

We have presented in this paper an approach which can combine a large set of appearance features and learn tracking parameters. The quantification of HOG descriptor reliability and the combination of color covariance, dominant color with spatial pyramid distance help to increase the robustness of the tracker for managing occlusion cases. The learning of feature significances for different video contexts also helps the tracking

algorithm to adapt itself to the context variation problem. The experimentation proves the effect of the feature weight learning, also the robustness of the proposed tracker compared to some other approaches in the state of the art. We propose in future work an automatic context detection to increase the auto-control capacity of the system.
